

EFFECTIVENESS OF ALVEOLITIS TREATMENT IN DIABETIC PATIENTS: A NEW APPROACH

Introduction: tooth extraction is the most common surgical procedure performed in outpatient dental practice. Typically, postoperative wounds heal without complications; however, some patients may experience inflammation of the socket, known as alveolitis. Key factors contributing to this inflammatory process include surgical trauma, the duration of the procedure, the presence of periapical infections, and underlying health conditions, particularly diabetes - a progressively worsening disease recognized globally as a non-infectious epidemic.

Aim of the study: the study aims to evaluate the effectiveness of our improved alveolitis treatment method in patients with diabetes.

Conclusions: dynamic monitoring of the cellular composition of secretions from the tooth socket post-extraction facilitates early diagnosis of alveolitis. Incorporating oral baths with lysomucoid into standard treatment protocols enhances the healing process in the socket.
